## What is the clutter?

Clutter refers to radio frequency (RF) echoes returned from targets which are uninteresting to the radar operators and interfere with the observation of useful signals.

Such targets include natural objects such as ground, sea, precipitations (rain, snow or hail), sand storms, animals (especially birds), atmospheric turbulence, and other atmospheric effects, such as ionosphere reflections and meteor trails.

Clutter may also be returned from man-made objects such as buildings and, intentionally, by radar countermeasures such as chaff.

We will focus particularly on sea and land (or ground) clutter

- Radar cross section (RCS)
- RCS per unit illuminated area,  $\sigma^0$  ( $\text{m}^2/\text{m}^2$ )
- RCS per unit illuminated volume,  $\eta$  ( $\text{m}^2/\text{m}^3$ )
- Radar equation and pattern-propagation factor F
- Sea clutter RCS and spikes
- Land clutter RCS
- Sea and land clutter statistics
- The compound-Gaussian model
- Clutter spectral models

# Clutter reflectivity

4

A perfectly smooth and flat conducting surface acts as a mirror, producing a coherent forward reflection, with the angle of incidence equal to the angle of reflection. If the surface has some roughness, the forward scatter component is reduced by diffuse, non-coherent scattering in other directions.

For monostatic radar, clutter is the diffuse backscatter in the direction towards the radar

- The IEEE Standard for RCS in square meters is

$$\sigma = 4\pi \frac{P_s}{\Omega p_i}$$

where

$P_s$  = power (watts) scattered in a specified direction from the target having RCS  $\sigma$

$\Omega$  = solid angle (steradians) over which  $P_s$  is scattered

$p_i$  = power density (watts/m<sup>2</sup>) of plane wave at target

## Range of RCS Values (dBm<sup>2</sup>)

- Echo power directly proportional to RCS
- **Factors that influence RCS:**  
size, shape, material composition, moisture content, surface coating and roughness, orientation, polarization, wavelength, multipath

RCS of common objects

# Normalized RCS $\sigma_0$

The normalized clutter reflectivity,  $\sigma_0$ , is defined as the total RCS,  $\sigma$ , of the scatterers in the illuminated patch, normalized by the area,  $A_c$ , of the patch and it is measured in units of  $\text{dBm}^2/\text{m}^2$ .

$$\sigma^0 = \sigma / A_c$$

$$A_c = \alpha \rho R \theta_{az} \sec(\phi_{gr})$$

range resolution

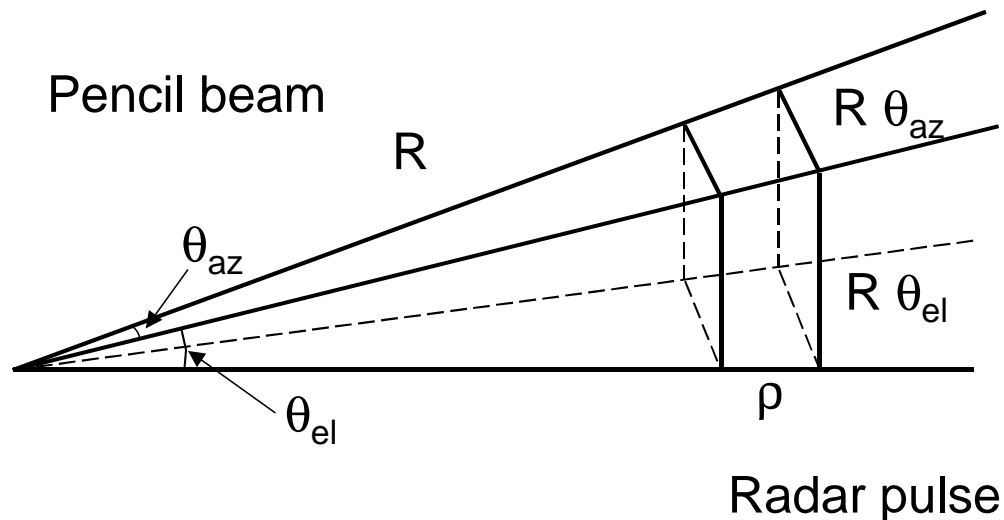

local grazing angle

The factor  $\alpha$  accounts for the actual compressed pulse shape and the azimuth beamshape

# Volume reflectivity $\eta$

8

The volume clutter reflectivity,  $\eta$ , is defined as the total RCS,  $\sigma$ , of the scatterers in the illuminated volume, normalized by the volume itself,  $V_c$ , and it is measured in units of  $\text{dBm}^2/\text{m}^3$ .

$$\eta = \sigma / V_c$$

$$V_c = \alpha \rho R^2 \theta_{az} \theta_{el}$$

one-way 3dB elevation beamwidth

- For monostatic radar, received power  $P_r$  from a target with RCS  $\sigma$  is

$$P_r = \frac{P_t G^2 \lambda^2}{(4\pi)^3 R^4} \sigma F^4$$

- $P_t$  = transmit power
- $G$  = antenna gain
- $R$  = distance of target from antenna
- $F$  = the pattern-propagation factor, the ratio of field strength at a point to that which would be present if free-space propagation had occurred

A clutter measurement provides either  $\sigma F^4$  or  $\sigma^0 F^4$ .  
Even so, normally the data are reported as being  $\sigma$  or  $\sigma^0$ .

## DISCRETE

- RCS depends on aspect angle, multipath environment, frequency, and polarization
- RCS values up to 30 dBm<sup>2</sup> are common
- RCS above 40 dBm<sup>2</sup> rare, except in built-up areas
- Nominal RCS values:
  - 60 dBm<sup>2</sup> very large ship or building
  - 50/40 dBm<sup>2</sup> large building or ship
  - 30/20 dBm<sup>2</sup> small building/house
  - 20/10 dBm<sup>2</sup> trucks/automobiles

## DISTRIBUTED

- Average RCS =  $s^0$  times  $A$ , where  $A$  is illuminated surface area (footprint) of a range-azimuth cell

# Sea clutter: Dependence on grazing angle

11

At near vertical incidence, the backscatter is quasi-specular and varies inversely with surface roughness with a maximum at vertical incidence for a perfectly smooth surface.

At medium grazing angles the reflectivity shows a lower dependence on grazing angle (plateau region).

Below some critical angle ( $\sim 10^\circ$ , depending on the roughness) the reflectivity reduces rapidly with smaller grazing angles (interference region, where propagation is strongly affected by multipath scattering and shadowing).

## Nathanson tables [Nat69]

- The "standard" beginning 1969, updated 1990
- HH and VV POLs;  $0.1^\circ, 0.3^\circ, 1^\circ, 3^\circ, 10^\circ, 30^\circ, 60^\circ$  grazing
- Many data sources, 60 different experiments
- UHF to millimeter wavelengths
- Reported by sea state up to state 6
- Averaged without separating by wind or wave direction
- Greatest uncertainties at lower frequencies and  $< 3^\circ$
- Reported RCS generally larger than typical because
  - (a) experimenters tend to report strongest clutter and
  - (b) over-water ducting enhances apparent RCS

[Nat69] F.E. Nathanson, *Radar Design Principles*, McGraw Hill, 1969

## GIT model [Hor78]

- Variables: radar wavelength, grazing angle, wind speed, wind direction from antenna boresight, wave height
- Employs separate equations: for HH and VV polarization, and for 1 to 10 GHz and 10 to 100 GHz
- The 1-10 GHz model based on data available for grazing angles of 0.1 to 10° and average wave heights up to 4 m (corresponds to significant wave heights of 6.3 m)
- Few liable  $\sigma^0 F^4$  data available at 3° grazing and below, and for dependencies on wind and wave directions
- Graphs from the model appear to give “best guesses” of  $\sigma^0 F^4$  versus grazing angles less than 10°

[Hor78] M.M. Horst, F.B. Dyer, M.T. Tuley, “Radar Sea Clutter Model”, *IEEE International Conf. Antennas and Propagation*, Nov. 1978, pp 6-10.

## GIT model: Wind speed dependence

- HH POL, 10 GHz
- Cross-wave direction, 2 m signif. wave height, winds 3, 5, 10, 20 m/s
- $\sigma^0 F^4$  increases with wind speed,
- Critical angle unchanged, because wave height assumed fixed.

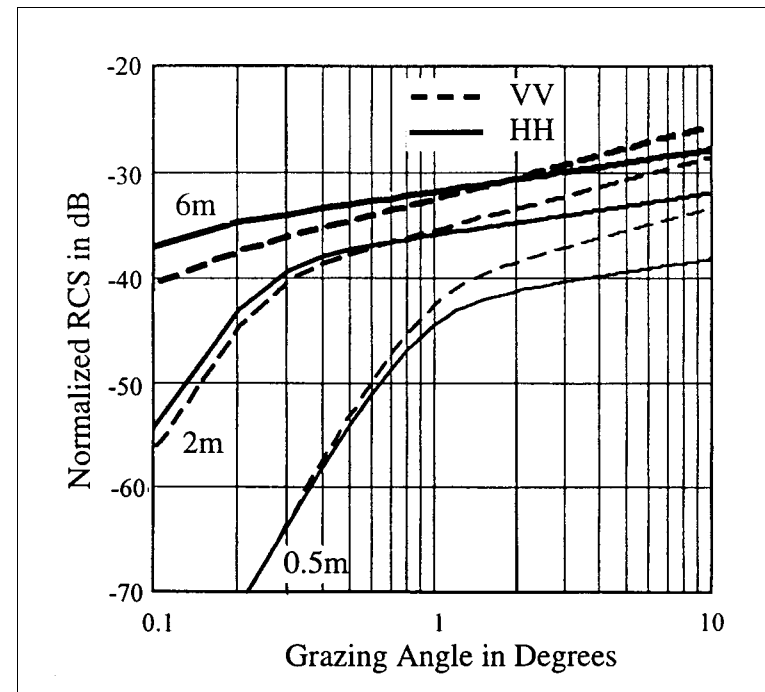

## GIT model: Dependence on significant wave height $h_{1/3}$

- HH POL, 10 GHz
- Cross-wave direction, 10 m/s wind speed,  $h_{1/3} = 0.5, 2, \text{ and } 6 \text{ m}$
- In plateau region,  $\sigma^0 F^4$  is independent of  $h_{1/3}$  (for fixed wind speed)
- $\sigma^0 F^4$  increases with  $h_{1/3}$  (multipath reduces critical angle) at angles  $< 1^\circ$

## GIT model: Comparison between HH and VV POL, 10 GHz

- Wind speed/wave height in equilibrium
- $\sigma^0 F^4$  increases with wind speed and  $h_{1/3}$
- HH/VV ratio increases with increased surface roughness and reduced grazing angle
- HH > VV at small angles under rough conditions at 1.25 and 10 GHz

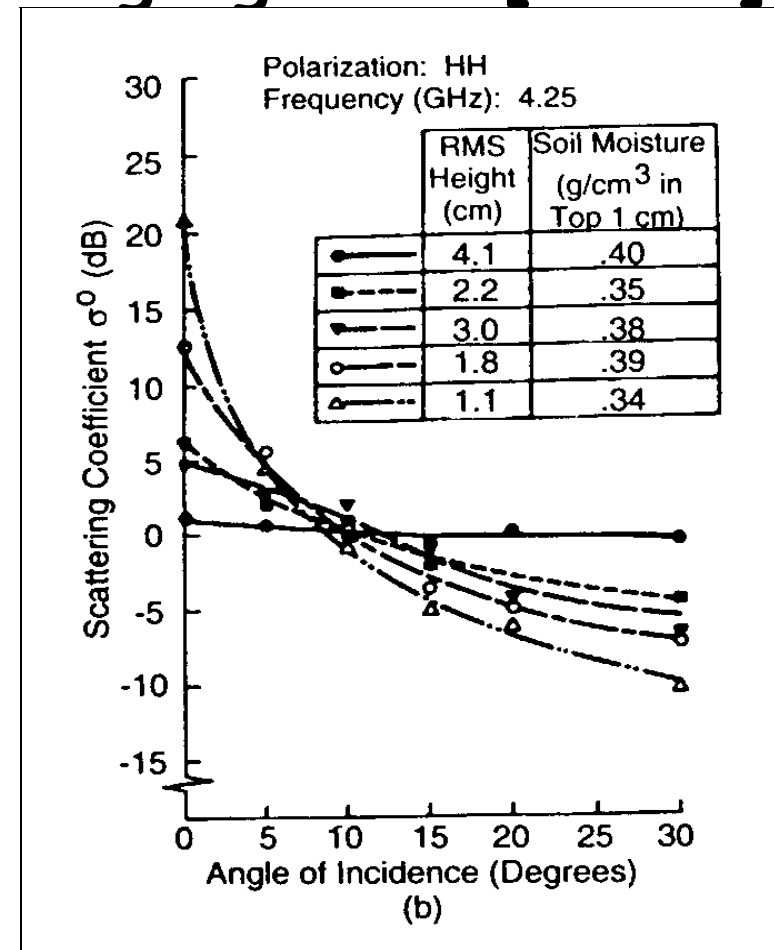

Bishop (1970) classified sea clutter at X-band into four types:

- **Noise-like-clutter** which appears similar to thermal noise with no apparent sign of periodicity;
- **Clumped clutter** which appears as a mixture of noise-like returns and discrete clumped clutter returns that often fades rapidly;
- **Spiky clutter** which consists largely of a collection of clumped returns with short persistence, e.g., 1 to 2s;
- **Correlated spiky clutter** consisting of persistent clumped returns. At any one time, an A-scope trace looks like a comb with semi-randomly spaced teeth. The whole pattern moves at speeds up to 40 knots. Individual spikes persisted for 10 to 40 s and the clutter level between spikes was virtually zero.

## $\sigma^0$ vs incidence angle for rough ground [Ula89]

- 4.25 GHz data, high moisture content
- $\sigma^0$  is insensitive to surface roughness at  $10^\circ$  ( $80^\circ$  grazing)
- Same insensitivity to roughness observed at  $80^\circ$  grazing in 1.1 GHz and 7.25 GHz data
- Same shapes but lower  $\sigma^0$  for dry conditions

[Ula89] Ulaby, F.T. and Dobson, M.C, *Handbook of Radar Scattering Statistics for Terrain*, Artech House, Norwood MA, 1989

## 37 Rural Sites [Bil02]

- Spatial averages of  $\sigma^0 F^4$  for  $\theta < 8^\circ$  grazing
- Larger spreads in  $\sigma^0 F^4$  at lower frequencies
- Resolution 150 & 15/36 m
- HH and VV polarizations
- At each frequency, the median spatial average is roughly -30 dB
- Note:  $\sigma^0 F^4$  can be larger at the lower frequencies

[Bil02] J.B. Billingsley, *Low-angle radar land clutter – Measurements and empirical models*, William Andrew Publishing, Norwich, NY, 2002.

# Clutter statistics: effect of spatial resolution 20

The scattered clutter can be written as the vector sum from  $N$  random scatterers

$$z = \sum_N \sqrt{\sigma_i} \exp[j\phi_i]$$

RCS of a single scatterer                      phase term

With low resolution radars,  $N$  is deterministic and very high in each illuminated cell. Through the application of the central limit theorem (CLT) the clutter returns  $z$  can be considered as Gaussian distributed, the amplitude  $r = |z|$  is Rayleigh distributed and the most important characteristic is the radar cross section.

$$p(r) = \frac{2r}{\sigma^2} \exp\left[-\frac{r^2}{\sigma^2}\right] u(r)$$

# Clutter statistics: effect of spatial resolution 21

This is not true with high resolution systems. With reduced cell size, the number of scatterers cannot be longer considered constant but random, then improved resolution reduces the average RCS per spatial resolution cell, but it increases the standard deviation of clutter amplitude versus range and cross-range and, in the case of sea clutter, versus time as well.

Jakeman and Pusey [Jak78] showed that a modification of the CLT to include random fluctuations of the number  $N$  of scatterers can give rise to the K distribution (for amplitude PDF):

$$Z = \frac{1}{\sqrt{\bar{N}}} \sum_{i=1}^N a_i e^{j\varphi_i} \xrightarrow{\bar{N} \rightarrow \infty} R = |Z|$$

2-D random walk

K distributed if  $N$  is a negative binomial r.v. (Gaussian distributed if  $N$  is deterministic, Poisson, or binomial)

$$\bar{N} = E\{N\}, \{a_i\} i.i.d., \{\varphi_i\} i.i.d.$$

# The compound-Gaussian model

22

In general, taking into account the variability of the local power  $\tau$ , that becomes itself a random variable, we obtain the so-called **compound-Gaussian** model, then

$$p(r | \tau) = \frac{2r}{\tau} \exp\left[-\frac{r^2}{\tau}\right] u(r)$$
$$p(r) = \int_0^{\infty} p(r | \tau) p(\tau) d\tau; \quad 0 \leq r \leq \infty$$

According to the CG model:

$$z(n) = \sqrt{\tau(n)}x(n)$$

$$x(n) = x_I(n) + jx_Q(n)$$

**Texture:** non negative random process, takes into account the local mean power

**Speckle:** complex Gaussian process, takes into account the local backscattering

Particular cases of CG model (amplitude PDF):

K (Gamma texture) →

$$p_R(r) = \frac{\sqrt{4\nu/\mu}}{2^{\nu-1}\Gamma(\nu)} \left( \sqrt{\frac{4\nu}{\mu}} r \right)^\nu K_{\nu-1} \left( \sqrt{\frac{4\nu}{\mu}} r \right) u(r)$$

GK (Generalized Gamma texture) →

$$p_R(r) = \frac{2br}{\Gamma(\nu)} \left( \frac{\nu}{\mu} \right)^{\nu b} \int_0^\infty \tau^{\nu b-2} \exp \left[ -\frac{r^2}{\tau} - \left( \frac{\nu}{\mu} \tau \right)^b \right] d\tau$$

LNT (log-normal texture) →

$$p_R(r) = \frac{r}{\sqrt{2\pi\sigma^2}} \int_0^\infty \frac{2}{\tau^2} \exp \left[ -\frac{r^2}{\tau} - \frac{1}{2\sigma^2} [\ln(\tau/\delta)]^2 \right] d\tau$$

W, Weibull →

$$p_R(r) = \frac{c}{b} \left( \frac{r}{b} \right)^{c-1} \exp \left[ -(r/b)^c \right] u(r)$$

## K-PDF (amplitude PDF)

- The order parameter  $v$  is a measure of clutter spikiness
- The clutter becomes spikier as  $v$  decreases
- Gaussian clutter:  $v \rightarrow \infty$

The K model is a special case of the compound-Gaussian model:  
 $N$  = negative binomial r.v.  
 $\tau$  (local clutter power) = Gamma distributed  
 Amplitude  $R$  = K distributed

## Gamma-PDF (texture PDF)

# The multidimensional compound-Gaussian model 25

- In practice, radars process  $M$  pulses at time, thus, to determine the optimal radar processor we need the  **$M$ -dimensional joint PDF**
- Since radar clutter is generally highly correlated, the joint PDF cannot be derived by simply taking the product of the marginal PDFs
- The appropriate multidimensional non-Gaussian model for use in radar detection studies must incorporate the following features:

- 1) it must account for the measured first-order statistics (i.e., the APDF should fit the experimental data)
- 2) it must incorporate pulse-to-pulse correlation between data samples
- 3) it must be chosen according to some criterion that clearly distinguishes it from the multitude of multidimensional non-Gaussian models, satisfying 1) and 2)

## The multidimensional compound-Gaussian model<sup>26</sup>

- If the Time-on-Target (ToT) is short, we can consider the texture as constant for the entire ToT, then the compound-Gaussian model degenerates into the **spherically invariant random process (SIRP)** proposed by Conte and Longo [Con87] for modeling the radar sea clutter. By sampling a SIRP we obtain a **spherically invariant random vector (SIRV)** whose PDF is given by

$$p_{\mathbf{z}}(\mathbf{z}) = \int_0^{\infty} \frac{1}{(\pi\tau)^M |\mathbf{M}|} \exp\left(-\frac{\mathbf{z}^H \mathbf{M}^{-1} \mathbf{z}}{\tau}\right) p_{\tau}(\tau) d\tau$$

where  $\mathbf{z}=[z_1 \ z_2 \ \dots \ z_M]^T$  is the  $M$ -dimensional complex vector representing the observed data.

- A random process that gives rise to such a multidimensional PDF can be physically interpreted in terms of a locally Gaussian process whose power level  $\tau$  is random.
- The PDF of the local power  $\tau$  is determined by the fluctuation model of the number  $N$  of scatterers.

- The PDF of a SIRV is a function of a non negative quadratic form:

$$q(\mathbf{z}) = (\mathbf{z} - \mathbf{m}_z)^H \mathbf{M}^{-1} (\mathbf{z} - \mathbf{m}_z)$$

- A SIRV is a random vector whose PDF is uniquely determined by the specification of a mean vector  $\mathbf{m}_z$ , a covariance matrix  $\mathbf{M}$ , and a characteristic first-order PDF  $p_\tau(\tau)$ :

$$p_z(\mathbf{z}) = \frac{1}{(\pi)^M |\mathbf{M}|} h_M(q(\mathbf{z}))$$

$h_M(q)$  must be positive and monotonically decreasing

$$h_M(q) = \int_0^\infty \tau^{-M} \exp\left(-\frac{q}{\tau}\right) p_\tau(\tau) d\tau$$

- First-order amplitude PDF:  $p_R(r) = \frac{r}{\sigma^2} h_1\left(\frac{r^2}{\sigma^2}\right)$ ,  $\sigma^2 = E\{R^2\} = E\{|z|^2\}$

- A SIRV is invariant under a linear transformation: if  $\mathbf{z}$  is a SIRV with characteristic PDF  $p_\tau(\tau)$ , then  $\mathbf{y} = \mathbf{A}\mathbf{z} + \mathbf{b}$  is a SIRV with the same characteristic PDF  $p_\tau(\tau)$ .

## First order statistics:

The homogeneity of sea allows to consider its spatial distribution equivalent to the temporal distribution. The same is not true for land clutter. The most common distributions for the sea clutter are the K, GK and Weibull.

Because of the large spatial variability of land clutter the statistics in space and time are different. The most common are in the table below.

	1st order
Time	Rayleigh, Rice, Weibull, Log-normal
Space	Weibull, Log-normal

- The question is: **How to specify the clutter covariance matrix and the power spectral density?**
- Correct spectral shape impacts clutter cancellation and target detection performance.
- The clutter spectrum is not concentrated at zero Doppler only, but spreads at higher frequencies.
- There are several reasons for the clutter spreading:
  - Wind-induced variations of the clutter reflectivity (sea waves, windblown vegetations, etc. ).
  - Amplitude modulation by the mechanically scanning antenna beam.
  - Pulse-to-pulse instabilities of the radar system components.
  - Transmitted frequency drift.
- The pulse-to-pulse fluctuation is generally referred to as **internal clutter motion (ICM)**.

The PSD is often modeled as having a Gaussian shape:

$$S_G(f) = S_{0G} \exp\left[-\frac{(f - m_f)^2}{2\sigma_f^2}\right]$$

This is usually a mathematical convenience rather than any attempt at realism. Often the Doppler spectrum will be strongly asymmetric and the mean Doppler shift,  $m_f$ , may not be zero. Clearly for land clutter  $m_f$  is usually zero, but for rain and sea clutter in general  $m_f \neq 0$  and will be dependent on the wind speed and direction.

From velocity/Doppler relationship  $v = f_D \lambda / 2$ ,  
 standard dev. of scatterer velocity is  $\sigma_v = \sigma_f \lambda / 2$

Wind changes bandwidths, but typical  $\sigma_v$  are

Rain/chaff  $\sigma_v \sim 1$  to  $2$  m/s

Sea  $\sigma_v \sim 1$  m/s

Land  $\sigma_v \sim 0$  to  $0.5$  m/s

The Gaussian PSD model was proposed by Barlow [Bar49] for **windblown clutter spectra**, for noncoherent radar systems and over limited spectral dynamic ranges (up to a level 20 dB below the peak level and to a maximum Doppler velocity of 0.67 m/s)

Essentially all modern measurements of ground clutter spectra, with increased sensitivity compared to those of Barlow, without exception show spectral shapes wider than Barlow's Gaussian in their tails

It had become theoretically well understood from 1965-67 on, that branch motion in windblown vegetation generates spectra wider than Gaussian

In a much referenced later report, Fishbein et al. [Fis67] introduced the power-law clutter spectral shape:

break-point Doppler frequency where the shape function is 3 dB below its peak zero-Doppler level

$$P_{ac}(f) = \frac{n \sin(\pi/n)}{2\pi f_c} \frac{1}{1 + (f/f_c)^n}$$

$n$  is the shape parameter

Common values of power-law exponent  $n$  used in PSD modeling are usually on the order of 3 or 4, but sometimes greater

The evidence that clutter spectra have power-law shapes over spectral dynamic ranges reaching 30 to 40 dB below zero-Doppler peaks is essentially empirical, not theoretical.

However, there is no simple physical model or fundamental underlying reason requiring clutter spectral shapes to be power law.

Recently, **Billingsley** [Bil91] showed that measurements at MIT-LL of windblown ground clutter power spectra to levels substantially lower than most earlier measurements (i.e., 60 to 80 dB below zero-Doppler peaks) indicate spectral shapes that fall off much more rapidly than constant power-law at the lower levels, at rates of decay approaching **exponential**:

$$P_{ac}(f) = \frac{\lambda\beta_e}{4} \exp\left(-\frac{\lambda\beta_e}{2}|f|\right)$$

$\lambda$  is the radar transmission wavelength and  $\beta_e$  is the exponential shape parameter

Then, recent studies have demonstrated that the ground clutter spectrum of windblown trees consists of three components:

- coherent component
- slow diffuse component
- fast-diffuse component

The *coherent component* was the results of radar returns from steady objects such as buildings, highways and from movable objects at rest.

The coherent component is at zero Doppler.

The *slow-diffuse component* is the consequence of motions of objects with moderate inertia (tree branches).

The slow-diffuse component occupies a relative narrow region around zero Doppler.

The spectrum is approximately symmetrical and its spectral density in dB scale decreases linearly with increasing absolute values of Doppler frequency.

The *fast-diffuse component* is the result of movements in light objects such as a tree leaves. This component has a spectral density similar to a band-limited noise. Its magnitude is usually compared to other components.

The spectral extent is of the same order as the Doppler shifts that corresponds to the wind speed.

Symbolic diagram of a ground-clutter spectral model.

## Spectral shapes having equal AC (Fluctuating) Power - Source: Billingsley (1996)

- Each spectrum for wind speed of about 20 mph
- The Gaussian shape reported by Barlow (1949)
- The power-law shape from Fishbein et al. (1967)
- The exponential shape from Billingsley and Larrabee (1987)

# Ground clutter spectra: X-band

37

A typical X-band ground-clutter spectrum.

A typical S-band ground-clutter spectrum.

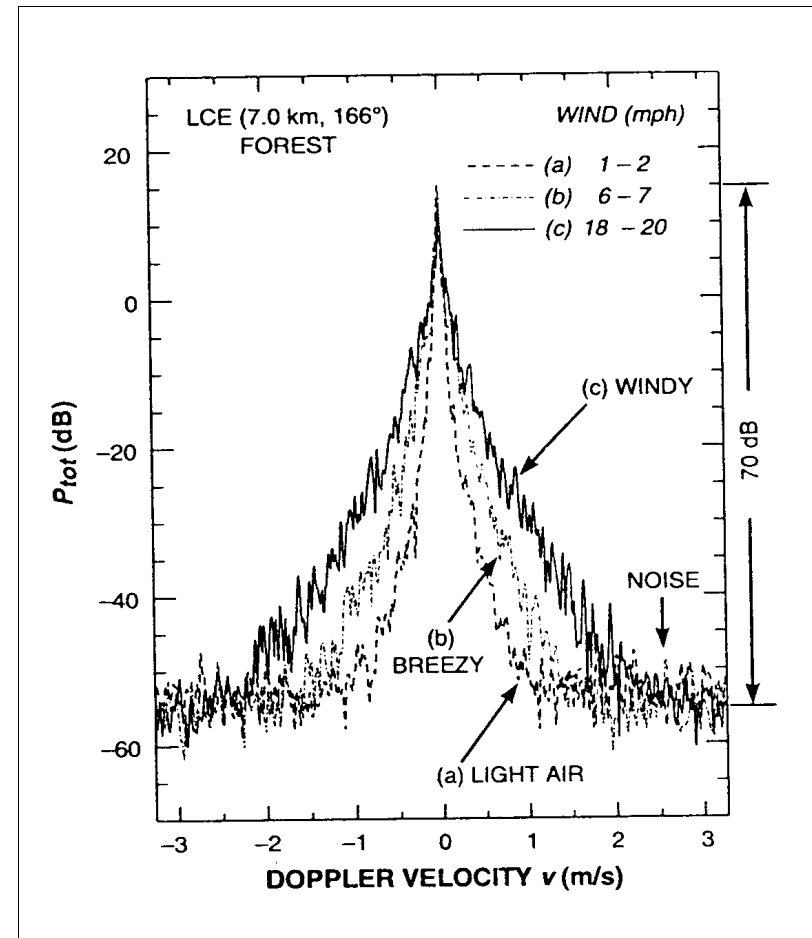

S-band

Variation of the spectral slope of the slow diffuse component over an observation interval.

- Approximate linear dependence of power density in dB versus velocity, for all wind speeds
- For VHF through X band, measured spectral shapes versus Doppler velocity found to be essentially the same

Source: Billingsley (1996).

The relative motion of the sea surface with respect to the radar causes an intrinsic Doppler shift of the return from individual scatterers.

Because the motion of the scattering elements have varying directions and speeds the total echo contains a spectrum of Doppler frequencies.

Two effects are of interest:

- the spectral shape and width
- the mean Doppler shift of the entire spectrum.

The spectrum of sea clutter is sometimes assumed to have Gaussian shape. An approximate relationship between the -3dB bandwidth  $\Delta f$  of the spectrum and sea state  $S$  (Douglas scale) has been derived by Nathanson:

$$\Delta f = 3.6 f_{0(\text{GHz})} S$$

The standard deviation of the Gaussian spectrum is related to  $\Delta f$  by the expression:

$$\sigma_f = 0.42 \Delta f$$

Recently more complex and realistic models have been proposed for sea clutter PSD. We are going to analyze them later on.

# **Radar Clutter: Live recorded data**

## Transmitter

- frequency agility (16 frequencies, X-band)
- H and V polarizations, switchable pulse-to-pulse
- pulse width 20 ns to 5000 ns
- PRF=0 to 20 KHz

## Receiver

- coherent receiver
- 2 linear receivers; H or V on each receiver
- quantization: 8 to 10 bits
- sample rate: 0 to 50 MHz
- BW=5.5 MHz

## Antenna

- parabolic dish (2.4 m)
- pencil beam (beamwidth 1.1°)
- grazing angle <1°, fixed or scanning

Source: Defense Research Establishment Ottawa.

The spikes have different behaviour in the two like-polarizations (HH and VV)

The dominant spikes on the HH record persist for about 1-3 s.

The vertically polarized returns appear to be a bit broader but less spiky

$$p_R(r) = \frac{1}{r\sqrt{2\pi\sigma^2}} \exp\left(-\frac{1}{2\sigma^2} [\ln(r/\delta)]^2\right) u(r)$$

W, Weibull

$$p_R(r) = \frac{c}{b} \left(\frac{r}{b}\right)^{c-1} \exp[-(r/b)^c] u(r)$$

K (Gamma texture)

$$p_R(r) = \frac{\sqrt{4\nu/\mu}}{2^{\nu-1}\Gamma(\nu)} \left(\sqrt{\frac{4\nu}{\mu}} r\right)^\nu K_{\nu-1}\left(\sqrt{\frac{4\nu}{\mu}} r\right) u(r)$$

GK (Generalized Gamma texture)

$$p_R(r) = \frac{2br}{\Gamma(\nu)} \left(\frac{\nu}{\mu}\right)^{\nu b} \int_0^\infty \tau^{\nu b-2} \exp\left[-\frac{r^2}{\tau} - \left(\frac{\nu}{\mu}\tau\right)^b\right] d\tau$$

LNT (log-normal texture)

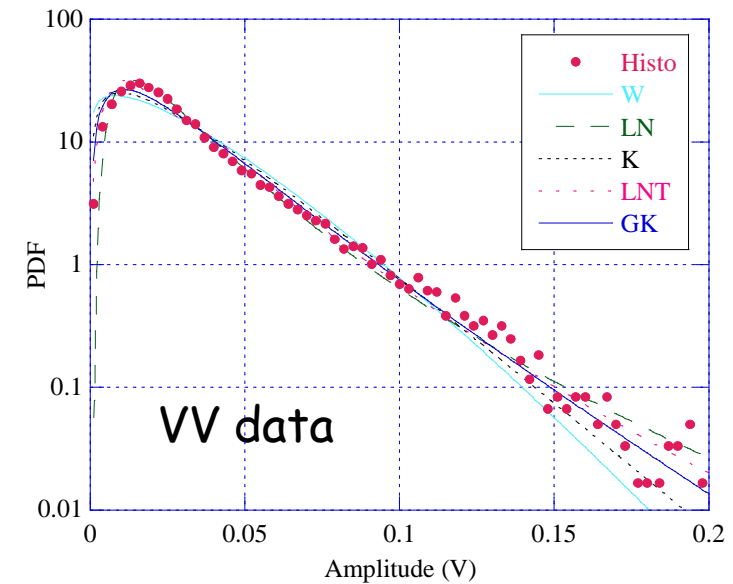

$$p_R(r) = \frac{r}{\sqrt{2\pi\sigma^2}} \int_0^\infty \frac{2}{\tau^2} \exp\left[-\frac{r^2}{\tau} - \frac{1}{2\sigma^2} [\ln(\tau/\delta)]^2\right] d\tau$$

- A histogram is a graphical representation used to plot density of data, and often for density estimation.
- A histogram consists of tabular frequencies, shown as adjacent rectangles, erected over discrete intervals (bins), with an area equal to the **frequency of the observations** in the interval. The height of a rectangle is also equal to the frequency density of the interval, i.e., the frequency divided by the width of the interval. The total area of the histogram is equal to the number of data.
- A histogram may also be normalized displaying relative frequencies. In that case the total area is 1. The bins must be adjacent, and often are chosen to be of the same size.

# Statistical Analysis: Results - 15 m

51

- With resolution of 60 m, 30 m, and 15 m a very good fitting with the GK-PDF.
- Negligible differences among polarizations

- With resolution of 9 m and 3 m histograms with very long tails
- Not big differences among polarizations, but generally HH data spikier than VV data

# Average spectral models

- ✓ *Capillary waves* with wavelengths on the order of centimetres or less. Generated by turbulent gusts of near surface wind; their restoring force is the surface tension.
- ✓ *Longer gravity waves* (sea or swell) with wavelengths ranging from a few hundred meters to less than a meter. Swells are produced by stable winds and their restoring force is the force of gravity.

- In the literature, it has been often assumed that the sea clutter has **Lorentzian** spectrum (i.e., autoregressive of order 1).
- **Autoregressive (AR)** models with the order  $P$  ranging from 2 to 5 have also been proposed for modelling radar clutter.
- For the sea surfaces some experimental analysis at small grazing angle,  $C$  and X-bands, indicate that the sea Doppler spectrum cannot be expressed by the Bragg mechanism only, but also by wave bunching (**super-events**).

■ Lee *et al.* showed that the spectral lineshapes can be decomposed into three **basis functions** which are **Lorentzian**, **Gaussian**, and **Voigtian** (convolution of the Gaussian and Lorentzian):

$$S(f) = \frac{\Gamma/2\pi^2}{(f - f_L)^2 + (\Gamma/2\pi)^2}$$

peak of the Lorentzian function

$\Gamma^{-1}$  = characteristic scatterer lifetime

$$S(f) = \frac{a}{\pi} \int_{-\infty}^{\infty} \frac{\exp(-x^2)}{\left(\frac{f - f_V}{f_{ve}} - x\right)^2 + a^2} dx$$

$a = \Gamma/2\pi f_{ve}$  shape parameter

$f_V$  = centre of the Voigt function

- The PSD can be estimated parametrically (or model-based) or non-parametrically, without any hypothesis on the model.
- Non parametrically, we used the **periodogram** defined as:

$$P(f) = \frac{|Z(f)|^2}{M}$$

- where  $Z(f)$  is the Fourier Transform of the data and  $M$  the number of samples.
- There are many variants of the periodogram (for instance, method of Welch, Blackman and Tukey) [see e.g. Stoica and Moses book on Power Spectral Analysis].

The spectrum is the sum of two basis functions among: the Gaussian, the Lorentzian, and the Voigtian, with different Doppler peaks.

**non-par: periodogram**  
**Gauss and Voigtian basis functions**

High peak (Voigtian): 450 Hz  
 Low peak (Gaussian): 320 Hz

High peak (Voigtian): 410 Hz  
 Low peak: (Gaussian): 250 Hz

- An Autoregressive process of order  $P$ ,  $AR(P)$ , is characterized by the difference equation:

$$Z(n) = \sum_{k=1}^P a_{P,k} Z(n-k) + W(n)$$

where the coefficients  $a_{P,k}$  are the process parameters, and  $W(n)$  is white noise

- For estimating the  $AR(P)$  parameters, we use the Yule-Walker equations

$$\begin{bmatrix} R_z(0) & R_z(1) & \cdots & R_z(P-1) \\ R_z(-1) & R_z(0) & & \vdots \\ \vdots & & \ddots & R_z(1) \\ R_z(1-P) & \cdots & R_z(-1) & R_z(0) \end{bmatrix} \begin{bmatrix} a_{P,1} \\ a_{P,2} \\ \vdots \\ a_{P,P} \end{bmatrix} = \begin{bmatrix} R_z(1) \\ R_z(2) \\ \vdots \\ R_z(P) \end{bmatrix}$$

$$\mathbf{R}\mathbf{a} = \mathbf{r}$$

- In our case, we don't know the "true" correlation of the clutter, so we estimate it as

$$\hat{R}_Z(m) = \frac{1}{N} \sum_{k=0}^{N-1-|m|} z(n)z^*(n+m)$$

We replace the estimated correlation to the true one and we solve the linear system

$$\hat{\mathbf{a}} = \hat{\mathbf{R}}^{-1} \hat{\mathbf{r}}$$

so obtaining an estimate of the characteristic parameters of the PSD.

We tried AR(P) with P=1 up to 16.

AR(3) model shows good fitting with data and seems to capture physical phenomena.

Good compromise between model complexity and fitting accuracy.

**Example of periodogram calculated on 60,000 HH polarized data.**

# X-band ground clutter data in open agricultural terrain

**VV polarization**

Black areas: high reflectivity  
(buildings, fencelines, trees, bushes aligned along roads)

White areas: low reflectivity  
(field surfaces)

The illuminated area was covered by agricultural crops (83%), deciduous trees (11%), lakes (4%), and rural farm buildings (2%).

2D clutter map

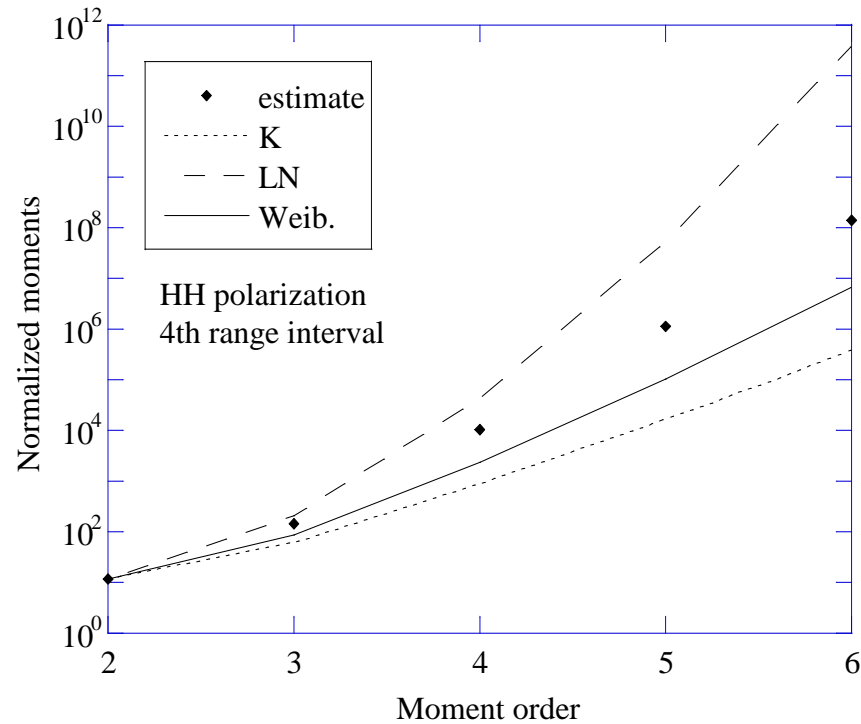

**The phase is uniformly distributed**  
(it may be not for DC offset, quantization effects, etc.)

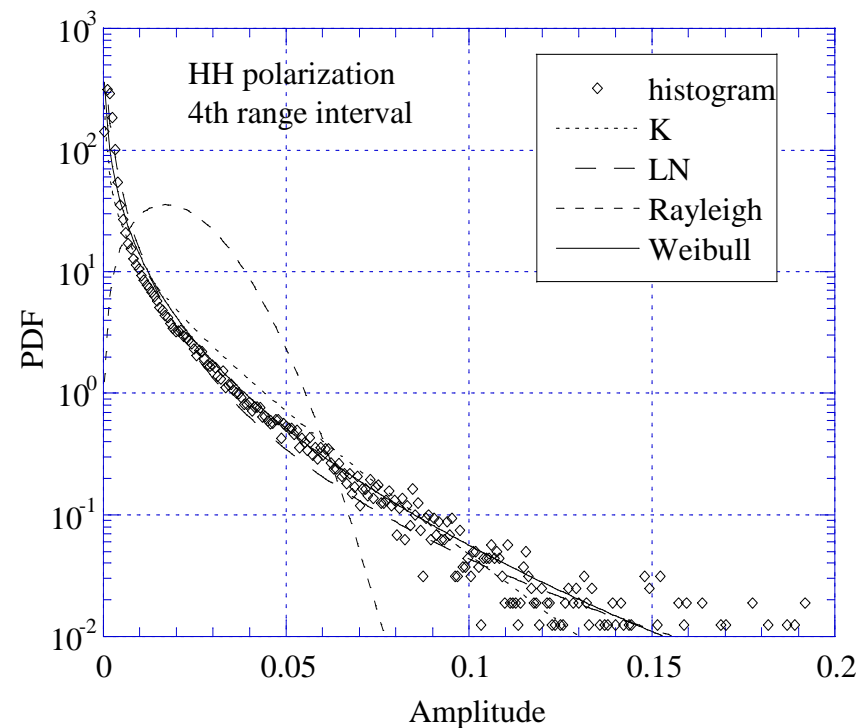

The analysis, performed on each range interval has shown that I and Q PDFs deviate considerably from Gaussian: **the clutter amplitude is not Rayleigh distributed**

1st and 2nd range intervals:  
the Weibull distribution  
provides the best fitting

3rd and 4th range intervals:  
the data show a behaviour that  
is intermediate between  
Weibull and log-normal

## Analyzed clutter data:

- recorded at Katahdin Hill site by Lincoln Laboratory.
- Phase One X-band stationary antenna.
- HH-polarization, PRF=500 Hz, 76 range gates.

## 3D power map

*Data set courtesy of Barrie Billingsley  
of MIT – Lincoln Laboratory*

**These data are Gaussian.**

PSD, 35th range cell.

Cell #35	Exp	Gauss	PL2	PL3
$\beta/\sigma f_c/f_c$	5.95 (Hz m) <sup>-1</sup>	23.63 Hz	1.02 Hz	6.33 Hz

Non-Linear Least Squares (NLLS) method is used for parameter estimation:

$$\theta_{Log-NLLS} = \arg \min_{\theta} \sum_i |Log_{10} P_{ac}(f_i, \theta) - Log_{10} S(f_i)|^2$$
